ABSTRACT: Storing solar energy is a vital component of using renewable energy sources to meet the growing demands of the global energy economy. Molecular solar thermal (MOST) energy storage is a promising means to store solar energy with on-demand energy release. The light-induced isomerization reaction of norbornadiene (**NBD**) to quadricyclane (**QC**) is of great interest because of the generally high energy storage density ($0.97 \, \text{MJ kg}^{-1}$) and long thermal reversion lifetime ($t_{1/2,300K}$ = 8346 years). However, the mechanistic details of the ultrafast excited-state [2 + 2]-cycloaddition are largely unknown due to the limitations of experimental techniques in resolving accurate excited-state molecular structures. We now present a full computational study on the excited-state deactivation mechanism of **NBD** and its dimethyl dicyano derivative (**DMDCNBD**) in the gas phase. Our multiconfigurational calculations and nonadiabatic molecular dynamics simulations have enumerated the possible pathways with 557 S_2 trajectories of **NBD** for 500 fs and 492 S_1 trajectories of **DMDCNBD** for 800 fs. The simulations predicted the S_2 and S_1 lifetimes of **NBD** (62 and 221 fs, respectively) and the S_1 lifetime of **DMDCNBD** (190 fs). The predicted quantum yields of **QC** and **DCQC** are 10 and 43%, respectively. Our simulations also show the mechanisms of forming other possible reaction products and their quantum yields.
1. INTRODUCTION

Sunlight is an essentially renewable and sustainable energy resource. The utilization of solar energy requires effective technologies to convert intermittent sunlight into steady electricity or fuel for regular usage. Efforts have been made to develop, for instance, solar cells,[1−6] CO_2 reductions,[7−10] water splitting,[11,12] energy-dense fuels,[13,14] photoswitches,[15−17] and solar thermal energy storage.[18] Among various prominent technologies, molecular solar thermal (MOST) energy storage provides a promising tool to store solar energy and release it on demand.[19−21] MOST devices are developed based on photoswitchable molecules. MOST materials isomerize from a thermodynamically stable structure to a metastable structure, storing the absorbed energy in strained chemical bonds. Many organic molecules have been investigated for MOST applications, such as azobenzene,[16,22−24] anthracene,[25,26] tetracarbonyl-fulvalene-diruthenium,[27−30] dihydroazulene/vinylheptafulvene (**DHA/VHF**),[31−34] bicyclooctadiene/tetracyclooctane (**BOD/TCO**),[35,36] and norbornadiene/quadricyclane (**NBD/QC**).[37−43] The **NBD/QC** system is one of the top candidates, where the **NBD** undergoes a [2 + 2]-photocycloaddition to the photoisomer **QC** (Figure 1).[44,45]

The thermal reversion of **QC** to **NBD** releases a storage energy of 88 kJ mol^{-1}, corresponding to a storage density of 0.97 MJ kg^{-1}.[35] The back reaction barrier of **QC** is about 138 kJ mol^{-1},[46] which leads to a half-life of 14 h at 140 °C (i.e.,

Figure 1. Illustration of solar thermal energy storage based on **NBD** and **QC** isomerization.

$t_{1/2,300K}$ = 8346 years).[47] Such a lifetime allows the **NBD/QC** system to store the accumulated solar energy effectively. However, the high energy of absorption maximum (200−230 nm[48,49]) and the modest quantum yield (QY) of **QC** (5%) could limit its efficiency for solar energy conversion.[20,41,42,50] Many studies have shown that the functionalization of the π_{CC} bonds of NBD can red-shift the absorption and increase the QY.[37,39,40,51−54] But the increased molecular weight of substituents reduces the energy storage density to 0.10−0.56 MJ kg^{-1}.[41] A high-throughput virtual screening studies on 3239 **NBDs**[55] and machine-learning-assisted screening of over 10^{25} substituted **NBDs** discovered only 15 candidates with absorption longer than 350 nm, storage density larger than 0.4 MJ kg^{-1}, and back reaction barriers exceeding 150 kJ mol^{-1} ($t_{1/2,300K}$ = 459 824 years).[56]

Literature reports on the photophysical properties and reaction energies provide important design features, but considerably less is known about the excited-state reaction mechanisms of **NBD** and its derivatives. The ultrafast photochemical **NBD → QC** interconversion has been the primary focus of computational and experimental elucidation of the low-lying absorption at 212 nm (5.85 eV) corresponding to an excitation to the 3s-Rydberg state.[49,57,58] The mechanistic studies are limited to the exploration of the excited-state potential energy surface (PES) and characterization of the S_1/S_0 minimum energy conical intersection (MECI).[59] The S_1/S_0 MECI shows a bond-forming geometry indicating an important role in the [2 + 2]-cycloaddition reactions. A grid-based quantum dynamics study of **NBD** observed $S_1 → S_0$ transition through the S_1/S_0 MECI, while the simulations were carried out considering 3 degrees of freedom.[60] Other reports described the substituent effects on the excitation energy, excited-state minimum energy path (MEP), and the energy storage of the functionalized **NBD**.[61,62] However, the excited-state dynamics of **NBD** that fully traverse the reaction coordinate from the initially excited **NBD** (Franck−Condon region) to product(s) have not been explored yet. In this work, we use nonadiabatic dynamics coupled with CASSCF calculations to study the deactivation pathways of photoexcited **NBD** and its dimethyl dicyano derivative **DMDCNBD** (Scheme 1). **DMDCNBD** was selected

as a model system of the related compound **TMDCNBD** (Figure 9) to learn how substituents affects the photodynamics of **NBD**. **TMDCNBD** has a red-shifted absorption spectrum due to the presence of the cyano groups, and it shows higher photoisomerization QYs to **QC** (57−96%),[63,64] suggesting that substituents might block cycloreversions and side reactions. We analyze the deactivation mechanism after photoexcitation. We also offer a mechanistic map showing other possible reaction products and their predicted quantum yields.

2. COMPUTATIONAL METHODS

We selected the CASSCF method for the gas-phase excitations and prepared a suitable active space. Previous experimental and theoretical studies on **NBD** found a low-lying absorption at 212 nm (5.85 eV) corresponding to an excitation to the 3s-Rydberg state.[49,57,58] Antol proposed a (4,5) active space of four π-electrons and four π-orbitals with restricted single excitations to an auxiliary 3s-orbital to compute the excited-state potential energy surface (PES) of **NBD**.[59] Recently, Remacle and co-workers included another 3p-orbital forming an (8,8) space to model the quantum dynamics of **NBD** over the eight electronic states.[60] Since we are interested in the photochemical reactions of **NBD** occurring in the low-lying states, we considered a (4,7) active space with 3s-, 3p$_x$-, and 3p$_y$-orbitals. The selection of these Rydberg orbitals was based on the lowest four excitations. We note a recent work by Marazzi and Pastore that used the same active space studying the excited-state PES of **NBD**.[65] We further benchmarked the excitations of **NBD** with time-dependent density functional theory (TDDFT) using the range-separated functional, ωB97XD[66] and equation of motion coupled cluster with singles and doubles (EOM-CCSD)[67] and the aug-cc-pVDZ basis sets.[68] Figure 2 illustrates the (4,7) active space computed with the six-state-averaged (SA6) CASSCF(4,7)/ANO-S-VDZP method. The ANO-S-VDZP basis set[69−72] has a quality generally comparable to aug-cc-pVDZ.[73]

The active space for **DMDCNBD** contains the four π-electrons and four π-orbitals involved in bond formations and additional four π-electrons and two π-orbitals of the cyano groups, forming an (8,6) active space. The selection of π-orbitals (Figure 3) was based on the TDDFT results at the ωB97XD/aug-cc-pVDZ level of theory.

The geometries of **NBD** and **DMDCNBD** were optimized with SA6-CASSCF(4,7)/ANO-S-VDZP and SA6-CASSCF(8,6)/ANO-S-VDZP, respectively. Hessian calculations confirmed the local minima with no imaginary frequencies. We assessed the quality of CASSCF excitation energies with the extended multistate complete active space second-order perturbation (XMS-CASPT2) method. We used OpenMolcas 19.11 in the CASSCF and XMS-CASPT2 calculations.[74] The TDDFT and EOM-CCSD calculations were performed with ORCA 4.2.0.[75]

The gas-phase photodynamics simulations used Tully's surface hopping method based on the product of the time-independent nonadiabatic couplings (NACs) and velocities.[76,77] We applied phase corrections at every timestep based on the NAC overlaps between two consecutive time steps.[78] To accelerate the simulations, we only considered the NACs between adjacent states and assumed zero coupling between nonadjacent states (e.g., states 1 and 3). The simulations ran in the microcanonical ensemble (NVE) and the simulation times are 500 and 800 fs for **NBD** and **DMDCNBD** with a timestep of 0.5 fs, respectively. The surface hopping calculations

[a]Experimental data and configurations are obtained from ref 57. Energies are in eV. For convenience, the $\pi_2 \rightarrow \pi_3^*$, $\pi_1 \rightarrow \pi_3^*$, and $(\pi_2 \rightarrow \pi_3^*)^2$ configurations are termed $\pi\pi^*$, $\pi\pi_2^*$, and doubly excited (DE), respectively.

integrated the nuclear amplitude with a step size of 0.02 fs (i.e., 25 substeps). We applied an energy-based decoherence correction of 0.1 hartree to the nuclear amplitude.[79] At surface hopping event, the momenta were rescaled isotropically to ensure energy conservation. The **NBD** trajectories started from the S_2-state, whereas the **DMDCNBD** trajectories started from the S_1-state.

800 initial conditions of **NBD** and **DMDCNBD** were sampled for gas-phase photodynamics simulations using the Wigner sampling at the zero-point energy level.[80,81] The trajectories that failed to converge the CASSCF calculations were removed from the analysis. The final number of trajectories was determined by ensuring (1) a converged QY prediction, and (2) the QY values were higher than the margin of error at the 95% confidence level (Figure S4). We also computed the vertical excitation energies of the Wigner-sampled initial conditions of **NBD** and **DMDCNBD** to simulate the gas-phase absorption spectra. The computed wavelengths were expanded with narrow Gaussian functions (i.e., full width at half-maximum of 8 nm) and scaled with the oscillator strengths.

3. RESULTS AND DISCUSSION

Table 1 summarizes the computed vertical excitations of **NBD** and the reported experimental results.

The TD-ωB97XD/aug-cc-pVDZ and EOM-CCSD/aug-cc-pVDZ calculations agree that the S_1 and S_2 are $\pi\pi^*$ and 3s-Rydberg states, respectively. The TD-ωB97XD/aug-cc-pVDZ calculation predicts a mixture of $\pi\pi^*$ and $\pi\pi_2^*$ states in S_3, whereas the EOM-CCSD/aug-cc-pVDZ calculation indicates a 3p$_y$-Rydberg state. This difference suggests a competing contribution of the valence and Rydberg excitations above 6 eV. The SA6-CASSCF(4,7)/ANO-S-VDZP calculations overestimate the excitation energies, as expected. They agree with the XMS(6)-CASPT2(4,7)/ANO-S-VDZP calculation and experimental results that S_1 is a $\pi\pi^*$ state and also suggest that the S_2 is a doubly excited (DE) $\pi\pi^*$ state, 0.03 eV lower than the S_3, the 3s-Rydberg state. The XMS(6)-CASPT2(4,7)/ANO-S-VDZP results confirm that the doubly excited (DE) state is a higher state (S_4). However, XMS(6)-CASPT2(4,7) predicts the S_2 to be a second $\pi\pi^*$ state ($\pi\pi_2^*$), which overestimates the energy of the 3s-Rydberg state (7.39 eV) compared to the experimental results (5.85 eV). The overestimation is caused by an insufficient diffuseness of the

ANO-S-VDZP basis set. For instance, the XMS(10)-CASPT2-(4,7) calculations with aug-cc-pVDZ predict that the S_1 and S_2 are $\pi\pi^*$ (4.70 eV) and 3s-Ryberg states (5.93 eV), respectively, in line with the experiments. Similar results are reported by Marazzi and Pastore using a large ANO-L basis set.[65] However, these methods lead to a considerably higher computational cost for the dynamics simulations. Therefore, we used SA6-CASSCF(4,7)/ANO-S-VDZP for the spectrum and dynamics simulations as a compromise between computational cost and quality.

We computed the gas-phase vertical excitation energies of 800 Wigner-sampled **NBD** structures to explore the nature of electronic excitations to the Franck−Condon (FC) regions. Figure 4 illustrates a convoluted spectrum with contributions from various excited-state electronic configurations.

The SA6-CASSCF(4,7)/ANO-S-VDZP calculations predict a broad S_1 absorption peak in 160−200 nm, centered at 180 nm, in line with the experimental report by Fuß et al.[49] S_1 is dominated by a $\pi\pi^*$ state (94%) mixed with a minor doubly excited (DE) state (6%). The computed intensity of

Figure 4. Simulated absorption spectrum for the first three bands of **NBD**. 800 structures were used to compute vertical excitation energies with SA6-CASSCF(4,7)/ANO-S-VDZP. The absorption bands are decomposed according to their excited-state electronic configurations (DE indicates a doubly excited $\pi\pi^*$ configuration).
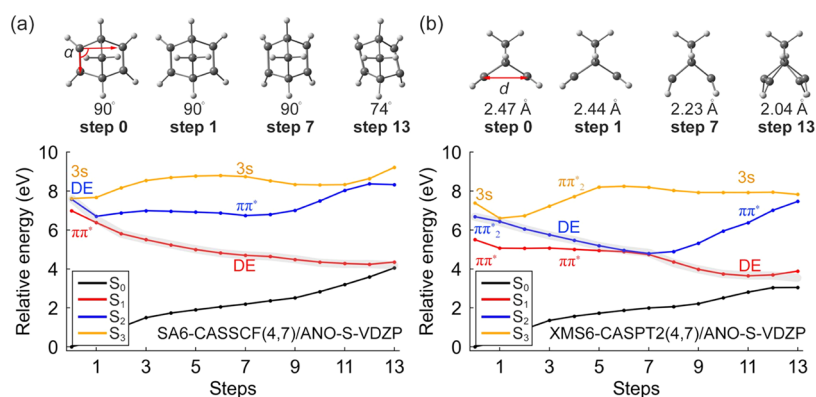

Figure 5. Minimum energy paths of **NBD** optimized with the SA6-CASSCF(4,7)/ANO-S-VDZP (a) and corrected with the XMS(6)-CASPT2(4,7)/ANO-S-VDZP (b). The minimization path follows the S_1 toward the S_1/S_0 MECI. The gray curves highlight possible S_2 relaxation pathways.

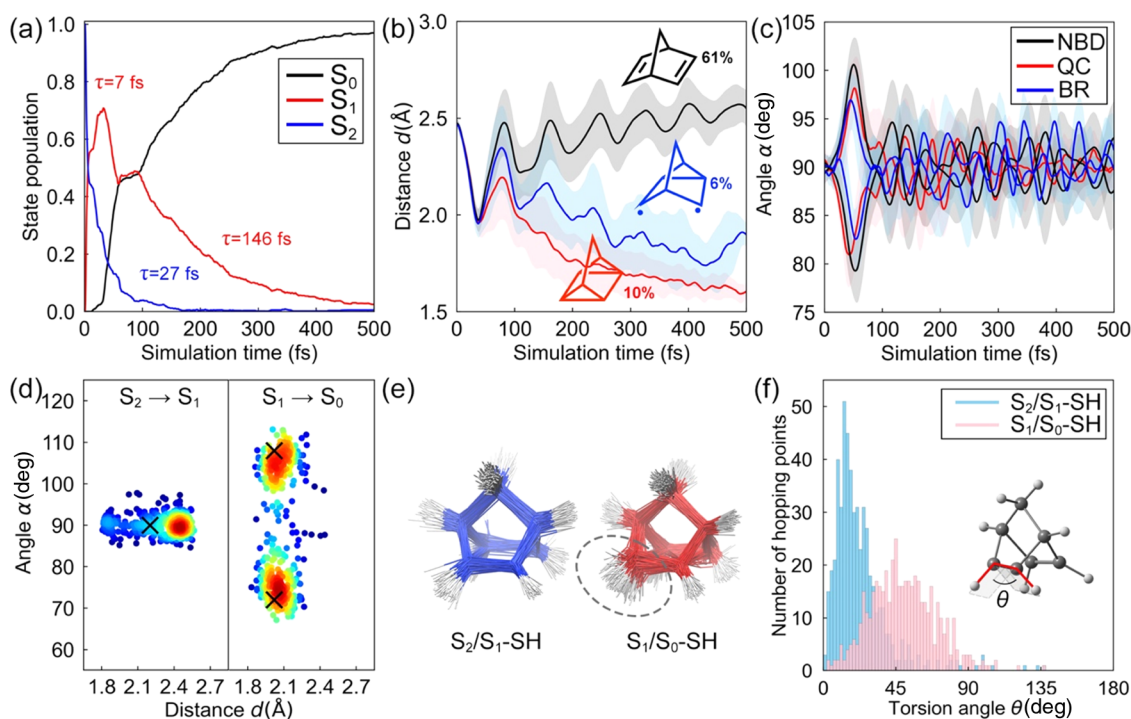

Figure 6. (a) State population, (b) average π_{CC}-distance, (c) rhomboidal angle, and (d) surface hopping distributions of 557 **NBD** trajectories in the gas phase. In panels (b) and (c), the shaded regions render a half standard deviation to the average values to show the diversity of the trajectories. In panel (d), the "X" denotes the positions of the S_2/S_1 and S_1/S_0 MECIs. The colors from blue to red represent the accumulation of the surface hopping points from low to high, evaluated by Gaussian kernel density estimation. (e) Overlays of the 200 randomly selected S_2/S_1 and S_1/S_0 surface hopping structures. The gray circle highlights the pyramidalization of the π_{CC} bond in the S_1/S_0 surface hopping structures. (f) Distributions of the torsion angle θ among the S_2/S_1 and S_1/S_0 surface hopping structures. The θ values in the S_2/S_1 and S_1/S_0-MECI are 0 and 32°, respectively.

absorption to S_1 is nonzero, suggesting that the $\pi\pi^*$ state is accessible from the nonequilibrium **NBD** geometries. The S_2 and S_3 peaks overlap from 150−180 nm. They show strong absorption intensities corresponding to the 3s-Rydberg state. The 3s-Rydberg state in S_2 is 40%, and the competing DE and $\pi\pi^*$ states are 46 and 14%, respectively. However, the DE and $\pi\pi^*$ intensities are considerably lower than the 3s-Rydberg state (Figure 4). S_3 is composed of the 3s-Rydberg state (60%), DE state (27%), and $3p_y$-Rydberg state (12%). The $3p_y$-Rydberg state leads to a shoulder at 150 nm. The simulated spectrum for S_2 qualitatively agrees with the experiments by Fuß and co-workers, where the irradiation populates both the 3s-Rydberg and the $\pi\pi^*$ states.[49]

The minimum energy path (MEP) in Figure 5 displays the steepest descent pathways from the FC point of **NBD**, indicating a pseudo-dominant path toward mechanistic critical points (e.g., minimum energy conical intersection). Following the S_3 and S_2 states, the MEPs quickly converged on an excited-state local minimum (Figures S1 and S2). In contrast, the MEP from the S_1-FC point provides an informative description of the nonradiative [2 + 2]-cycloaddition pathway from **NBD** to **QC**. Figure 5a,b compares the S_1 MEP optimized with the SA6-CASSCF(4,7)/ANO-S-VDZP method and those corrected with XMS(6)-CASPT2(4,7)/ANO-S-VDZP.

We identified two parameters to quantify the structural changes along the reaction coordinate: a rhomboidal angle among the bond-forming carbon, α, and a distance between the π_{CC} bonds, d (Figure S3). In the S_1-FC region, d and α are 2.47 Å and 90°, respectively. Figure 5a shows that the MEP along the S_1 slightly decreases the π_{CC}-distance ($\Delta d = 0.03$ Å) at step 1, which switches the state order between the $\pi\pi^*$ and the DE states. In the following steps, the DE state dominates the S_1 state. The geometrical parameters resemble a rhomboidal shape ($\alpha = 74°$ and $d = 2.04$ Å), consistent with the previously reported S_1/S_0-MECI structures by Antol.[59] The XMS(6)-CASPT2(4,7)/ANO-S-VDZP MEP suggests the $\pi\pi^*$ and DE states are separated by the 3s-Rydberg and $\pi\pi_2^*$ states at the S_1-FC geometry (Figure 5b). The DE state appears in S_2 at the first step as the energy decreases with the π_{CC}-distance. The DE state then leads to an S_2/S_1 crossing point at step 7 with $d = 2.23$ Å (Figure 5b). This indicates that the SA6-CASSCF(4,7)/ANO-S-VDZP overestimates the π_{CC}-distance at the S_2/S_1 crossing point. Nevertheless, the SA6-CASSCF-(4,7)/ANO-S-VDZP and XMS(6)-CASPT2(4,7)/ANO-S-VDZP results agree that the DE state in S_2 drives the excited-state PES to the S_1/S_0 crossing point for the [2 + 2]-cycloaddition of **NBD**.

The excitation energies to the S_2 and S_3 states are nearly degenerate (Table 1), and their electronic excitations are mixtures of 3s-Rydberg and DE states (Figure 4). We, therefore, expect that the **NBD** trajectories starting from S_3 would undergo rapid internal conversion to S_2 with negligible structural changes. Hence, we started 500 fs gas-phase photodynamics simulations from S_2. We collected 557 trajectories to obtain statistically converged results (Figures 6 and S4).

After 500 fs, 97% of the trajectories were in the S_0 state and 2 and 1% remained in S_1 and S_2, respectively. Figure 6a illustrates an exponential decay of the S_2 population with a time constant $\tau = 27$ fs. The trajectories excited to the 3s-Rydberg state show $\tau = 28$ fs (Figure S4a). The S_1 ($\pi\pi^*$ state) population increases to a local maximum of 0.71 at 32 fs ($\tau = 7$ fs). It rises to the second maximum of 0.49 at 88 fs due to the time-discontinuous $S_1 \rightarrow S_0$ decay as explained below. The overall $S_1 \rightarrow S_0$ decay leads to $\tau = 146$ fs. The previous experiment by Fuß and co-workers measured a longer time constant of the 3s-Rydberg state ($\tau = 420$ fs) than the $\pi\pi^*$ state ($\tau = 55$ fs).[49] However, our results suggest that the lifetime of the 3s-Rydberg state ($\tau = 27$ fs) is shorter than that of the $\pi\pi^*$ state ($\tau = 146$ fs). The numerical difference in the lifetime may result from a local overestimation of the S_1-PES energy near the FC region with SA6-CASSCF(4,7)/ANO-S-VDZP (compare Figure 5a,b). Such energy overestimation decreases the S_2–S_1 energy gap, thus accelerating the $S_2 \rightarrow S_1$ decay and causing a slower $S_1 \rightarrow S_0$ decay.

Figure 6b,c illustrates substantial structural changes of **NBD** during the 500 fs simulations. Structural parameters d and α have average values of 2.47 Å and 90° at the start of the trajectories, respectively. In all trajectories, the π_{CC}-distance is instantaneously reduced below 2 Å within the first 50 fs (Figure 6b). At the same time, the rhomboidal angles undergo notable oscillations between 80 and 100° (Figure 6c). The trajectories then split into three pathways: (1) reversion to **NBD** (61%), (2) formation of the **QC** product (10%), and (3) formation of a singlet biradical (**BR**) intermediate (6%). The predicted QY of **QC** (10%) is in reasonable agreement with

the experimental QY (5%).[20,41,42,50] A **C**/**NBD** formation ratio of 1:6 is also predicted.

The structural changes of **NBD** originated from the nonradiative decay through the S_2/S_1, and subsequent S_1/S_0 crossing seams are depicted in Figure 6d where a scatter plot of the three-dimensional (3D) geometries of the hopping points projected onto two reaction coordinates (d and α) is shown. The majority of the S_2/S_1 hopping points (centered at $d = 2.45$ Å) are structurally related to those in the S_2-FC region (centered at $d = 2.47$ Å). In contrast, a minority of those trajectories passing through the S_2/S_1 surface hopping points access the S_2/S_1-MECI ($d = 2.20$ Å and $\alpha = 90°$) region. We interpret that the rapid $S_2 \rightarrow S_1$ decay (Figure 6a) arises from the geometric proximity of the structures in the S_2-FC region and S_2/S_1 crossing seam. The S_1/S_0 surface hopping is concentrated near $d = 2.06$ Å with a symmetric angular distribution at $\alpha = 74$ and 105° (Figure 6d). The symmetric angular distribution indicates two equivalent S_1/S_0 crossing seams around the S_1/S_0-MECI at $d = 2.02$ Å and $\alpha = 72°$ (108°). The distinct structural differences between the S_1/S_0 surface hopping points and the S_2-FC points explain the time-discontinuous $S_1 \rightarrow S_0$ decay. The $S_1 \rightarrow S_0$ decay depends on the π_{CC} distances and the rhomboidal angle. During the dynamics, the $S_1 \rightarrow S_0$ decay stops when the S_1 trajectories return to the FC regions with long π_{CC} distances and 90° of rhomboidal angle, e.g., at 90 fs. However, the $S_2 \rightarrow S_1$ decay requires almost no geometrical changes. It constantly populates the S_1 state, which leads to the second maximum of the S_1 population. Figure 6e shows an overlay of the S_2/S_1 and S_1/S_0 hopping points. The S_2/S_1-SH structures resemble a midpoint of the linear interpolated structures between **NBD** and **QC**. However, most S_1/S_0-SH structures feature a pyramidalized π_{CC} bond. We quantify the extent of the pyramidalization with an HCCH torsion angle, θ. Figure 6f illustrates a histogram of θ in the trajectories to describe the π_{CC}-pyramidalization distribution at the S_1/S_0 crossing seam. The θ ranges from 3 to 137° at the S_2/S_1 hopping points, but the average value is 23°. In the S_1/S_0-SH structures, θ ranges from 1 to 137°, and the average value increases to 49°. These results agree with prior assertions that π_{CC} pyramidalization affords easier access to S_1/S_0 conical intersections. Similar phenomena have been reported in the conical intersection and surface hopping structures of photoexcited conjugated molecules.[82−84]

The ultrafast dynamics and substantial structural changes predicted in our NAMD trajectories are in very good agreement with the experimental observations[49] and can be interpreted in terms of an impulsive photoactivated mechanism.[85,86] Upon photon excitation, those vibrational modes that are most coupled to the electronic excitation, i.e., showing high vibronic couplings, will take a bigger fraction of the electronic energy and therefore be activated. A Huang−Rhys factor analysis (Figure 7a) shows that, for the $S_0 \rightarrow S_2$ transition, the highest vibronic coupling is predicted for the wing-flapping vibration (the two ethylenic halves moving apart). The Huang−Rhys factors were computed at the SA6-CASSCF(4,7)/ANO-S-VDZP level and using FCclasses3 software.[87] The photoactivation of the wing-flapping vibration suggests a substantial change in d and α coordinates as observed during the first 50 fs of our NAMD trajectories (Figure 6b,c) and also in experiments.[49] An electron density difference map, computed at the same level of theory for the $S_0 \rightarrow S_2$ transition, shows that the sudden or impulsive photoactivation of the wing-flapping mode is triggered by a
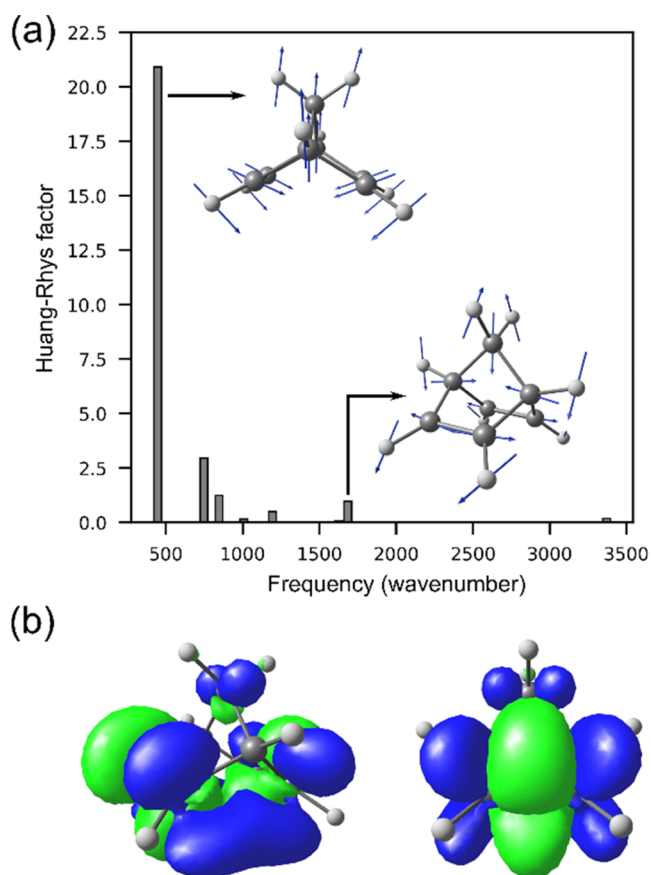

Figure 7. (a) Huang−Rhys factors and (b) electronic density difference map computed for the S$_0$ → S$_2$ transition of **NBD** at the SA6-CASSCF(4,7)/ANO-S-VDZP level of theory. In panel (b), two views of the electronic density difference map are shown. The green and blue colors represent electronic density depletion and accumulation, respectively.

Figure 8. Side reactions observed in the gas-phase **NBD** trajectories with the ratios of products or intermediates. The methylene bridge and the newly formed σ_{CC}-bonds in **QC** are highlighted in blue and red, respectively.

cycloaddition pathways (10%). The predicted side reactions suggest a qualitative agreement with the photodegradation of substituted **NBDs** observed in experiments when the excitation localized on the **NBD** unit is probed.[88]

We continue to explore the substituent effects on **NBD** that might change the photophysical properties and block the competing cycloreversions and rearrangements. The literature reports that the cyano groups can red-shift the absorption wavelength of **NBD** to 334−366 nm with enhanced **QC** yields of 57−96% (Figure 9).[63,64] A recent work also investigated the spectroscopic properties of cyano-substituted **NBD**.[89]

Figure 9. Literature reported [2 + 2]-cycloaddition of the cyano-substituted **NBD** systems at different wavelengths. [a]Ref 63. [b]Ref 64.

density depletion between the ethylenic bonds and density accumulation between the π_{CC} bonds (Figure 7b). The change of the bonding energy between the atoms launches nuclear motions in which the distance between the ethylenic halves d decreases and the distance between the ethylenic bonds increases. From Figure 7a, it is also noted that the stretching mode between the ethylenic C atoms is significantly coupled to the electronic transition.

The wing-flapping mode represents a good approximation to the barrierless coordinate driving the deactivation from FC-S$_2$ **NBD** to the S$_2$/S$_1$ and S$_1$/S$_0$ MECIs. Experiments have also shown that this mode plays an important role in **NBD** deactivation.[49] The wing-flapping vibrational period, computed with SA6-CASSCF(4,7)/ANO-S-VDZP, is 75 fs, in very good agreement with the experiments (80 fs).[58] Thus, deactivation from S$_2$ occurs within the first vibrational period supporting the conclusion that the wing-flapping mode must be impulsively activated upon photon absorption.

Besides the major products, our photodynamics simulations also identified several side reaction rearrangement pathways (Figure 8). These reactions feature breaking σ_{CC}-bonds; CASSCF rotates the σ_{CC}-orbitals into the (4,7) active space as the σ_{CC}-bonds stretch beyond their equilibrium geometries during the trajectories. The QYs for the ring-opening and rearrangement pathways are relatively minor (2−6%) compared to the reversion to **NBD** (61%) and the [2 + 2]-
For simplicity, we generated the structure of **DMDCNBD** by replacing the methyl group with H on the bridge-head carbon based on the analogous **TMDCNBD** in Figure 9. The dimethyl and dicyano groups on each side provide donor−acceptor-type electronic inductions. Table 2 collects the computed vertical excitation energies and electronic transitions for **DMDCNBD**.

The TD-ωB97XD/aug-cc-pVDZ calculation shows the S$_1$ energy of 4.03 eV, which is comparable to the experimental value reported for its analogue **TMDCNBD** (3.71 eV).[88] The S$_1$ and S$_2$ are described by $\pi-\pi^*$ excitations between the π_{CC}-bonds; the S$_3$ excites one electron from the π_{CN} to the π_{CC}^*-orbital. The SA6-CASSCF(8,6)/ANO-S-VDZP calculations overestimate the excitation energies compared to the XMS(6)-

Table 2. Vertical Excitation Energies with the Principal Electronic Configurations of DMDCNBD Calculated with the Relaxed Geometry in the Ground State

	S_1		S_2		S_3	
ωB97XD/aug-cc-pVDZ	4.03	$\pi_4 \rightarrow \pi_5{}^*$	5.16	$\pi_3 \rightarrow \pi_5{}^*$	5.88	$\pi_2 \rightarrow \pi_5{}^*$
SA6-CASSCF(8,6)/ANO-S-VDZP	5.68	$\pi_4 \rightarrow \pi_5{}^*$	7.30	$\pi_2 \rightarrow \pi_5{}^*$	7.40	$\pi_3 \rightarrow \pi_5{}^*$
						$\pi_4 \rightarrow \pi_5{}^*$
XMS(6)-CASPT2(8,6)/ANO-S-VDZP	4.33	$\pi_4 \rightarrow \pi_5{}^*$	5.70	$\pi_3 \rightarrow \pi_5{}^*$	6.70	$\pi_2 \rightarrow \pi_5{}^*$
Figure 10. (a) State population, (b) average π_{CC}-distance, and (c) surface hopping distributions of 492 **DMDCNBD** trajectories in the gas phase. In panel (b), the shaded regions render a half standard deviation to the average values to show the diversity of the trajectories. In panel (c), the "X" denotes the positions of the S_1/S_0 MECIs. The colors from blue to red represent the accumulation of the surface hopping points from low to high, evaluated by Gaussian kernel density estimation. Overlays of the 200 randomly selected S_1/S_0 surface hopping structures are shown inside panel (c). The gray circle highlights the pyramidalization of the π_{CC} bond.

CASPT2(8,6)/ANO-S-VDZP results. Both methods predict the same $\pi-\pi^*$ excitation for S_1. However, the π_{CN} excitation is underestimated to S_2 by SA6-CASSCF(8,6)/ANO-S-VDZP and S_3 becomes a doubly excited state. The S_2 and S_3 description by XMS(6)-CASPT2(8,6)/ANO-S-VDZP results agree with TD-ωB97XD/aug-cc-pVDZ. Together, the vertical excitation calculations show that the substitution with cyano groups substantially lowers the excitation energy and eliminates the contribution of Rydberg excitations. Considering the large S_1/S_2 state energy gap, the SA6-CASSCF(8,6)/ANO-S-VDZP method is reasonable for studying the $S_1 \rightarrow S_0$ decay and subsequent photochemical reaction pathways.

The vertical excitations to the FC regions of **DMDCNBD** present two separate absorptions without Rydberg character (Figure S5). The first peak corresponds to the S_1 excitation, and the second peak covers the excitation to S_2-S_4. As such, our photodynamics simulations for **DMDCNBD** start at S_1 assuming initial excitations via a feasible light source (e.g., 254 nm, 4.8 eV). The simulation time is 800 fs. We collected 492 trajectories to obtain statistically converged results (Figures 10 and S6).

In 800 fs, 98% of the trajectories finished in the S_0 state and 2% in S_1. Figure 9a plots the S_1 population dynamics with a time constant τ = 190 fs. This time constant is longer than the values for **NBD**, suggesting that the substituent effects slow the $S_1 \rightarrow S_0$ decay. This finding agrees with a recent study on the ultrafast dynamics of substituted **NBD**s that shows that the excited-state lifetimes are notably increased.[87] Figure 9b illustrates the trajectories toward **DMDCQC** and back to **DMDCNBD**. The bifurcation takes place when the π_{CC}-distances are longer than 2 Å, where the rhomboidal angle distribute within 85−95° (Figure S6a). The **DMDCQC** forms immediately as the π_{CC}-bond length reduces. The predicted yields **DMDCNBD** and **DMDCQC** are 49 and 43%, respectively, resulting in a 1:1 ratio of **QC**/**NBD**. The **DMDCQC** yield is comparable to the reported one for its analogue **TMDCQC**, 57% at 366 nm (Figure 9). These

findings indicate the substituent groups facilitate the [2 + 2]-cycloaddition. Moreover, the singlet biradical intermediate observed in **NBD** decreases to 1% and the overall side products decrease to 9% (Figure S7). These results support our argument that the substituent groups block the cycloreversions and rearrangements.

Figure 9c shows a scatter plot for the geometrical distributions of the S_1/S_0 hopping point structures. The S_1/S_0 surface hopping display symmetric angular distribution at α = 80 and 102° with d = 2.00 Å. The average π_{CC} distance at the S_1/S_0 hopping points is shorter than that at the trajectory bifurcation (>2 Å). This result suggests the substituent effects favor the [2 + 2]-cycloaddition, where the trajectories tend to form **DMDCQC** even before approaching the S_1/S_0 crossing seam around the S_1/S_0-MECI at d = 1.99 Å and α = 75° (105°). The overlay of the S_1/S_0 hopping points highlights the pyramidalized π_{CC} bond that we observed in the unsubstituted **NBD**. Collectively, our photodynamics simulations of **NBD** show the substituent effects that considerably increase the chemoselectivity of [2 + 2]-cycloaddition raising the QY of **QC**.

4. CONCLUSIONS

We have performed photodynamics simulations with CASSCF calculations to elucidate the deactivation mechanisms of photoexcited **NBD**. The vertical excitation energies reveal the significant role of Rydberg states in the absorption of unsubstituted **NBD**, in line with previous experimental and computational studies. Substitution with methyl and cyano groups eliminate the Rydberg excitation resulting in dominant $\pi\pi^*$ configurations. We propagated 577 trajectories of **NBD** from the bright S_2 state in 500 fs, effectively connecting the FC region to the product region, which identified products beyond **QC**. Besides forming the rhomboidal structures at the S_1/S_0 surface hopping points, we also observed the pyramidalization of the π_{CC} bonds, promoting the nonradiative decay. The predicted QYs of **NBD**, **QC**, and **BR** are 61, 10, and 6%,

respectively. We performed photodynamics simulations for another 492 trajectories for **DMDCNBD** to reveal the substituent effects on the photochemical reaction mechanisms of **NBD**. The trajectories show that **DMDCNBD** undergoes the same mechanism as **NBD**, forming a rhomboidal structure with pyramidalized π_{CC} bonds at the S_1/S_0 crossing seam. However, the trajectories of **DMDCNBD** bifurcate faster than those of the unsubstituted **NBD**, showing strong preference for [2 + 2]-cycloaddition reactions. The predicted QYs of **DMDCNBD** and **DMDCQC** are 49 and 43%, respectively, indicating that the substituent effects increase the QY of **QC**. Moreover, the overall yields of the side products are considerably reduced, supporting our conclusion that the substituent effects can block competing pathways.
